

How AI debt financing impacts duration supply and interest rates

February 10, 2020

Financing needs related to AI data center investments are likely to be large and persistent. While the overall economics of such investments remain a topic of much debate, the duration supply implications for U.S. interest rate markets have received less attention. Issuance of long-term investment-grade corporate bonds, swapping of floating rate loans from private credit investors, and possible crowding out of financial firms' long duration supply channels to watch. The divergence between the long end of the curve and long-term swap spreads is indicative of these flows and their impacts.

Introduction

Artificial intelligence (AI) promises to be a transformative technology with the potential to reshape the labor market and the economy. Its capabilities and impacts have been the subject of much study and debate, including by several of our colleagues at the Dallas Fed (see [here](#) and [here](#)). Growth in its capabilities and adoption has driven capital expenditure for several years. But from the somewhat rosy perspective of U.S. fixed income markets, AI has only recently burst forth onto the stage.

It is generally accepted that the scale of investment in data centers with the computational capacity to deliver AI technologies to end users is extremely large. Several different estimates place this number between \$1 trillion and \$5 trillion over the next three to five years (Chart 1). While a significant portion of the initial investment (estimated by various equity analysts and industry watchers) to be around \$300 billion to \$400 billion to date since 2021 appears to have been internally funded by hyperscalers (1) from retained earnings, these firms have begun tapping more recently to public and private debt markets. Issuance from these firms and others participating in the AI buildup has been both large and long in duration. Financing transactions in private markets are less observable, but several examples of structured debt balances have been reported to have been originated in the financial press.

Synthetic duration supply: Data center investors and operators are likely to seek fixed-rate financing for long terms, given the long lives of their assets (2). While issuance in corporate bond markets can readily accommodate these needs, borrowing from other sources (e.g., private credit markets) is much more likely to be floating rate. Because of the risk preference of investors in these markets. This means that data center managers are likely to pay lower swap in such transactions with pay-fixed swaps to synthetically transform these liabilities into fixed-rate term loans. A stylized illustration of how this works is shown in Chart 3.

Such pay-fixed swaps would effectively represent a form of synthetic duration supply to the rates market. Anecdotal evidence from market participants suggests that this may have been available in the fourth quarter of 2020, possibly totaling as much as \$10 billion in 10-year equivalents of bond issuance or more. Much like actual issuance of long duration Treasury, this flow of supply should not be the major long-term yield level higher and the yield curve steeper. But unlike actual Treasury market duration supply (which would, *ceteris paribus*, chop up Treasury relative to swaps), this synthetic duration supply should have Treasury's color term swap, since it ought to preserve yields higher relative to Treasury yields. This subtle difference is how synthetic duration supply impacts swap spreads vis-à-vis Treasury supply suggests a potential empirical approach to isolating the existence and scale of such transactions.

Duration supply in the form of Treasury might be expected to chop up Treasury versus swaps, while the supply effects we have discussed in this note might to reduce Treasury relative to swaps.

One way to look for evidence of AI-driven duration supply is by searching for an emerging divergence between the response of curve slopes and swap spreads in longer maturity markets to term premium. We do this in Chart 3 by measuring the sensitivity of the 10-year to 30-year Treasury term premium as well as the sensitivity of 30-year yield spread over swap rate to 10-year term premiums (3). As seen in the chart, the 10-year to 30-year swap curve slope has become increasingly sensitive to these duration measures of 10-year term premium, suggesting a growing role for long end duration supply. At the same time, the sensitivity of 30-year yield spread over swap rate to term premium has declined for two of the three measures while rising modestly for the third. Taken together, this is evidence of a divergence between the response of the yield curve slope and swap spreads at the long end, which is exactly what might be expected in the presence of synthetic duration supply from AI financing.

Substitution effects: It is conceivable that hyperscalers' issuance will partly crowd out supply from other investment-grade issuers, including financial firms that are currently the dominant issuers in the investment-grade market (4). Should this occur, the mere substitution of technology financing for financials (holding overall quantity of supply constant) would effectively translate into incremental duration supply (or more precisely, incremental negative duration demand) to the market as a whole and for the Treasury market in particular. This is because of a somewhat underappreciated risk effect of swapped issuance by financial firms, which effectively transfers the transfer of duration risk from the U.S. Treasury to corporate bond investors. Financial firms tend to prefer floating-rate liabilities. Therefore, they typically transform their corporate bond issuance into floating-rate liabilities by paying the bonds with interest-free swaps. In doing so, they are effectively buying duration from other investors, who in turn buy duration from Treasury investors holding asset-swapped Treasuries. The overall effect in the financial markets results in corporate bond investors buying duration from the Treasury market while providing funding to financial firms. A stylized schematic of the flow of duration in such transactions is shown in Chart 4.

Conclusions

Despite the relatively large scale of corporate debt markets, the Treasury market has historically been where the bulk of interest rate duration risk is supplied and traded. Although this will continue to be the case for the foreseeable future, data center financing looks likely to achieve significant additional duration risk to the rates market through a combination of direct bond issuance, swap transactions to lengthen the duration of floating-rate borrowings, and the potential displacement of financial firms who typically buy duration effects against their own debt issuance. The growing significance of these channels could weaken long-standing empirical relationships between the long-end Treasury curve slope and long-maturity swap spreads that persisted during long historical periods when duration supply came mostly through Treasury. A divergence between long end swap spreads and curve slopes is indicative of such new Treasury duration supply effects, which observers must account for when attempting to attribute long-end curve and swap spread moves to fiscal, monetary and regulatory policy drivers.

Notes

1. The term "hyperscalers" has become commonly used to refer collectively to large technology and cloud infrastructure firms such as Google, Microsoft, Open AI, Meta, Amazon, Netflix and Apple.
2. AI data center investments are estimated to involve a blend of very long-lived assets such as physical infrastructure and equipment, which are commonly depreciated over 10 to 17 years or more, and investments in semiconductors, which are being depreciated over five to six years by major technology firms, according to media reports and Securities and Exchange Commission filings.
3. Financial markets accounted for about 10 percent of all investment-grade supply in 2020.
4. Since yield curve slopes and asset swap spreads of Treasury may be impacted by several factors, a direct comparison may not help identify supply effects. However, since duration supply is likely to impact term premium regardless of channel, examining the sensitivity of yield curve slope as well as Treasury yield spread over swap to term premium is a way to examine how duration supply may be differently impacting these two market variables. Moreover, since there are many different measures of term premium, we apply only one framework to these commonly used measures. These measures of term premium are all based on the 10-year curve.

Data center financing will supply duration through multiple channels

The financing of AI-related data centers promises to supply significant duration into fixed income markets through a combination of direct effects, duration risk transfer via swap activity and displacement effects. The supply through these channels carries with it implications for the yield curve slope and level of term premium.

Direct effects: If recent issuance in investment-grade markets is an indication of things to come, corporate bond issuance related to AI investments could become a significant source of duration supply in U.S. fixed income markets. As Chart 2 shows, recent issuance from AI-related firms has been both large and concentrated in long maturities. The long duration of such issuance likely reflects the fact that the underlying assets being financed are long-lived, with underlying economics that do not vary with interest rates over the course of a business cycle. As a result, fixed-rate liabilities would be preferred by the borrower in order to lower interest volatility. Well-structured estimates of AI-related investment-grade issuance very much needed but are estimated to be \$300 billion for the year, which could result in new duration supply of as much as \$300 billion in 10-year equivalents over the course of 2020, or about an eighth of the duration supply from U.S. Treasury issuance.

Chart 2 AI-related debt issuance surged in 2020
